Motivation
Alzheimer’s Disease (AD) is one of the most common brain degenerations, with a decline mainly in episodic memory at an early stage and loss of broader cognitive functions subsequently. Currently, there is no effective treatment for AD. Although early-stage AD have been cured in amnesic mice through optogenetic stimulation, electrical stimulation could be more viable for accomplishing a memory recovery device for AD patients. In this project, we aim to retrieve memory in amnesic mice by electrical stimulation, which facilitates future clinic trials and helps record time-evolution of memory when pairing with electrical recording.

The Mechanism of Memory
The mechanism of episodic memory consists of four stages:

- **Encoding**: The perceived sensations from different sensory areas are combined and integrated into one single experience in the hippocampus, which leads to the formation of short-term memory.
- **Consolidation**: Long-term potentiation strengthens the synaptic connections between neurons (synaptic consolidation); hippocampus-dependent memory gradually becomes hippocampus-independent system consolidation.
- **Storage**: Memory engrams distributed throughout the cortex are formed to store the memory.
- **Retrieval**: The corresponding engram cells are reconnected with the presence of a proper stimulus.

Project Timeline
- Off-the-shelf (OS) chips and electrodes will be purchased and constructed to test the practicability of recording the electric signals in neuron cells after optical engram consolidation.
- Homemade (HM) electrodes will be fabricated, then tested and adjusted together with off-the shelf chips.
- Homemade chips will be fabricated, then tested and adjusted with homemade electrodes.
- Experiments involving foot shock trainings and tests will be carried out with optogenetic and electrical stimuli, along with signal processing.
- Further issues will be explored, e.g. the time evolution of memory consolidation.

Experimental Plan
A. Artificial memory recall with optogenetics-assisted electrical stimulation

B. Artificial memory recall with electrical stimulation only

C. Natural memory recall with optogenetics-assisted electrical stimulation

D. Natural memory recall with electrical stimulation only

Conclusion
In this project, we aim to (1) retrieve memory in mice with early-stage AD, and (2) reveal the time-evolution process of memory consolidation.

A new way of electrically treating AD will be demonstrated, with the advantages of easy realization and control. Meanwhile, the chronic recording of memory consolidation will help unravel the mechanism of memory formation.
